Introduction

The aim of clinical practice guidelines is to provide physicians with the best available evidence on particular issues and recommendations for the best standards of care. They help health professionals weigh the benefits and the risks of available diagnostic or therapeutic options. Randomised clinical trial (RCT) data on the management of thyroid cancer (TC) are relatively scarce, and the quality of available evidence is suboptimal. Retrospective analyses of treatment efficacy frequently show favourable outcomes, but it is difficult to discern the extent to which these results are due to the natural history of the disease. The number of cases retrospectively analysed is not an index of the quality of the data or the absence of biases. Consequently, large, well-planned RCTs managed within a network of coordinated centres are urgently needed.

The main goals of any cancer treatment are to improve overall survival (OS) and quality of life (QoL). Persistent disease in low-risk TC patients is often associated with prolonged survival. The indolent behaviour of the tumours in these individuals—the vast majority of the patients seen by clinicians—argues for the use of less aggressive diagnostic and therapeutic approaches than those reserved for higher-risk patients. Therefore, clinical practice guidelines are also intended to provide oncologists with cost-effective strategies that will minimise the risks associated with overtreatment.

Incidence and epidemiology

The last three decades have witnessed steady, worldwide increases in the incidence of TC [1, 2]. Figures from the European Network of Cancer Registries show estimated incidence rates among females in 2012 that were approximately threefold higher than those for males (9.3 and 3.1 cases per 100 000 person-years, respectively) [1]. Rates vary widely from country to country, with the highest figures (per 100 000 person-years) reported in Lithuania (15.5), Italy (13.5), Austria (12.4), Croatia (11.4) and Luxembourg (11.1). Estimated TC-related mortality rates, by contrast, are low (0.7 and 0.5 cases per 100 000 person-years for women and men, respectively) with considerably less regional and temporal variation [3].

The rising incidence rates are almost entirely due to the increased diagnosis of differentiated thyroid cancers (DTCs) and papillary thyroid cancers (PTCs) in particular. Incidence rates for follicular (FTC), anaplastic (ATC) and medullary (MTC) thyroid cancers have remained relatively stable over the past 30 years. The expanding use of imaging techniques, biopsy procedures [e.g. fine-needle aspiration (FNA)] and medical surveillance, along with improved access to healthcare, has facilitated the detection of small, subclinical PTCs [4]. The resulting overdiagnosis has invariably been accompanied by overtreatment [5]. According to the United States Preventive Services Task Force, the risks associated with TC screening in asymptomatic adults are likely to
outweigh its potential benefits [6]. Support is also growing for more conservative, risk-tailored strategies for TC management (including watchful waiting) [7–10].

DTC and poorly differentiated TC

Diagnosis and pathology/molecular biology

The diagnostic work-up of DTCs (including poorly differentiated forms) comprises pre- and postoperative pathological and molecular assessments. Preoperative FNA for cytology is not required for nodules measuring ≤1 cm. Decisions to aspirate larger nodules should be guided by lesion size and sonographic appearance [8]. Cytology findings are classified into diagnostic categories associated with different risks of malignancy [11]. Most malignant thyroid tumours can be identified microscopically. Notable exceptions are FTCs and the newly defined ‘non-invasive follicular thyroid neoplasm with papillary-like nuclear features’ (NIFTP), which are usually classified as indeterminate in the various thyroid cytology reporting schemes [12]. FNA-based diagnosis of poorly differentiated carcinoma is also challenging unless there is obviously increased mitotic activity and/or necrosis. FNA diagnosis can be facilitated by assessment of malignancy markers (including proteins commonly overexpressed in tumours, e.g. HBME1 or galectin-3) and molecular alterations specifically associated with malignancy (e.g. BRAF mutations, RET fusions, other novel gene alterations). Specifically designed gene panels are reportedly useful for identifying malignancy when cytology samples are morphologically indeterminate [13].

Resected DTCs are histologically classified according to the World Health Organization (WHO) criteria (updated in 2017—Table 1). Based on clinical evidence of their low-grade behaviour during long-term follow-up, encapsulated non-invasive follicular PTC variants are now referred to as NIFTPs. They account for up to 20% of cases in Europe [14]. Elimination of the term ‘carcinoma’ from the definition of this PTC variant underscores its excellent prognosis: NIFTP is associated with no reports of cancer-related deaths and an estimated risk of recurrence of <1%. This new entity shows partial overlap with the group of tumours defined in Europe as ‘well-differentiated tumours of uncertain malignant potential’ [15]. Diagnosis of NIFTP requires a scrupulous pathological examination of the follicular-pattern nodule to confidently exclude the presence of capsular invasion (even microscopic) and papillary formations. RAS but not BRAF mutations characterise NIFTPs. Correct identification of NIFTPs should reduce the unnecessary use of radical surgical procedures and the needless administration of radioactive iodine (RAI) after a completion thyroidectomy. NIFTP follow-up strategies should mimic those of very-low-risk carcinomas (see following sections). There are numerous other PTC variants, including some that are particularly aggressive and associated with higher tumour stages and lymph node metastases at diagnosis. The best-known of these are the tall cell, columnar, hobnail and solid variants [16, 17].

The WHO currently recommends reporting FTCs as ‘minimally invasive’ when capsular penetration is present without vascular involvement (a condition associated with an extremely good prognosis). The terms ‘angioinvasive’ and ‘widely invasive’ should be reserved for follicular cancers with neoplastic emboli involving <4 or ≥4 blood vessels, respectively.

The diagnostic criteria for poorly differentiated carcinomas remain controversial. A consensus conference in 2006 yielded the Turin proposal [18], which restricts this diagnosis to invasive tumours with a solid/trabecular/insular growth pattern plus at least one of the following:

- mitotic index ≥3 per 10 high-power fields;
- necrosis;
- convoluted nuclei (slightly smaller and darker than those typically seen in PTC, with irregular contours).

This definition delimits a category of TCs that behave aggressively while maintaining some degree of functional differentiation (e.g. thyroglobulin (Tg) production).

Hürthle cell carcinomas are no longer classified as ‘follicular tumours’, which are generally much less aggressive and less likely to present with lymph node metastases [16]. Hürthle cell carcinomas associated with extensive vascular and/or capsular invasion should be managed like other high-risk carcinomas (see following sections). ‘Pure’ Hürthle cell carcinomas (i.e., those with a Hürthle-cell component exceeding 75%) also present molecular abnormalities that distinguish them from conventional follicular carcinomas. As for oncocytic PTCs and oncocytic variants of poorly differentiated carcinomas, they are no more aggressive than their conventional counterparts.

Molecular profiling has distinguished two major classes of PTCs characterised by BRAF-predominant and RAS-predominant molecular signatures (Table 1) [19]. BRAF V600E mutations are frequently reported in a subgroup of PTCs with more aggressive clinicopathological behaviours, but the need for routine BRAF genotyping of PTCs has not been established. The fatal forms of non-ATC are generally PTC variants harbouring BRAF or RAS mutations plus other genomic alterations (e.g. mutations involving the TERT promoter, TP53, POLE, PI3K/AKT/mTOR pathway effectors, SWI/SNF subunits and/or histone methyltransferases), some of which are potential therapeutic targets [20]. The molecular profiles of follicular and Hürthle cell carcinomas are less well-defined. Work is underway to define the genomic and transcriptomic profiles of poorly differentiated and anaplastic TCs [21, 22].

Staging and risk assessment

Mortality risk

The Union for International Cancer Control (UICC) tumour, node, metastasis (TNM) classification of malignant tumours stages lesions based on their mortality risks. The eighth edition [23] introduced important changes for thyroid tumours, including the downstaging of extrathyroidal extension that is not macroscopically evident (pT3b) (Table 2). Primaries with extrathyroidal spread that is exclusively microscopic are now staged solely on the basis of tumour size as pT1, pT2 or pT3a. TNM staging requires a complete review of prognostically relevant morphological and immune-phenotypic parameters [20]. A checklist containing these parameters can be included in the final pathology report [IV, A] to supply details on the extent of invasion (capsular versus vascular, including number of affected vessels), tumour size and architecture, presence of necrosis, proliferative activity, etc. [10].

**Risk of persistent or recurrent disease.** Table 3 summarises the system developed in 2015 by the American Thyroid Association (ATA) to estimate the risk of persistent or recurrent TC based on data available shortly after treatment of the primary cancer [8, 24–26]. These criteria have now been revised and refined based on emerging evidence. The likelihood of persistent/recurrent disease after an apparently complete resection depends on several factors. The overall estimated risk of recurrence ranges from 1% to 55% and is classified as low (≤5%), intermediate (6%–20%) or high (≥20%). A high-quality pathology report is crucial for proper risk stratification.

The initial risk class assignment is revised during follow-up to reflect the evolution of the disease and responses to treatments (dynamic risk stratification) [IV, A] [27–30]. Treatment responses are defined as excellent, biochemical incomplete, structural incomplete or indeterminate based on imaging findings [mainly neck ultrasound (US)] and serum Tg and anti-Tg antibody (TgAb) levels (see Table 4) [8].

**Primary tumour management**

**Surgery.** Primary tumour management will be determined by the results of the preoperative risk assessment (Figure 1). Active US surveillance of the thyroid and neck lymph nodes (every 6–12 months) can be proposed for unifocal papillary microcarcinomas (≤10 mm) with no evidence of extracapsular extension or lymph node metastases [III, B] [31]. In these cases, the only known predictor of significant tumour growth (≥3 mm) or the onset of lymph node metastasis is age (10-year estimated risks: 36% in patients <30 years old, 14% in those aged 30–50, 6% in patients 50–60 years old) [32].

For other TCs, total thyroidectomy is still considered the standard surgical treatment. Two large database studies on surgical management strategies found that, for selected low-risk tumours (T1a–T1b–T2, N0), lobectomy alone does not reduce OS [IV, B] [33, 34], but it may be associated with a slightly higher local recurrence [8]. However, even large database studies are subject to biases. In risk-benefit analyses, it is important to recall that total thyroidectomy can cause recurrent laryngeal nerve injury (2.5%, bilateral in rare cases) and temporary or permanent hypoparathyroidism (8.1%) [35]. The risk (even when done by high-volume surgeons) is almost twice that of lobectomy alone, and postoperative complications are generally more likely with low-volume surgeons [36].

The use of prophylactic central neck dissection for low-risk tumours (T1b–T2, N0) varies from centre to centre [IV, C] [37–39]. Evidence of its effect on recurrence-free survival is conflicting, and there is no high-level evidence for or against its usefulness for low-risk tumours. Studies supporting prophylactic neck dissection for low-risk tumours have shown moderate reductions in central neck recurrence (5%–10%) but no improvement in OS. Prophylactic neck dissection does allow more complete staging of neck nodes, including identification of micrometastases not visible on preoperative US, and this information can be used to refine the prognosis and guide subsequent treatment and follow-up. Risks, however, include temporary hypoparathyroidism and overdiagnosis and overtreatment of subclinical micrometastases. The potential benefits of prophylactic neck dissection for low-risk tumours are now being evaluated in an RCT (NCT03570021—ESTIMABL3). For more invasive tumours (T3–T4), prophylactic neck dissection may improve regional control [IV, C] [40].

**RAI therapy.** RAI is administered after total thyroidectomy for several reasons:

- to eliminate the normal thyroid remnant, thereby ensuring undetectable serum Tg levels (in the absence of neoplastic tissue), which facilitate follow-up (remnant ablation);
- to irradiate presumed foci of neoplastic cells, thereby reducing the recurrence risk (adjuvant therapy); and/or

The pT and pN categories correspond to the T and N categories.

pN0 histological examination of a selective neck dissection specimen will ordinarily include 6 or more lymph nodes. If the lymph nodes are negative, but the number ordinarily examined is not met, classify as pN0.

The eighth edition of the UICC TNM staging system introduced several changes compared with the seventh edition. The main changes are noted with superscript numbers and are described in detail as follows:

1. Any T is accepted for ATC, in the previous edition, ATCs were only staged as T4a (limited to the thyroid) or T4b (extended beyond thyroid capsule).
2. Minor extrathyroidal extension was removed from the definition of T3 disease.
3,4 Two new categories, T3a and T3b, were introduced.
5 N1a was expanded to include the upper mediastinum (previously included in the N1b category).
6 The age cut-off at diagnosis used for staging was increased from 45 to 55 years.
7 In patients with papillary, follicular, Hurthle cell and poorly differentiated carcinomas, the T3, N1a and N1b categories were downstaged from stages III–IVa to stage II.
8 Including papillary, follicular, Hurthle cell, poorly differentiated, anaplastic and medullary carcinomas.
9 Including papillary, follicular, Hurthle cell and poorly differentiated carcinomas.

<sup>a</sup>Based on the 2015 ATA risk stratification staging system [8].
<sup>b</sup>All tumour sizes refer to largest diameter.
<sup>c</sup>Aggressive histologies: tall cell, hobnail variant, columnar cell carcinoma, squamous differentiation, diffuse sclerosing variant, solid/trabecular variant.
<sup>d</sup>If the tumour is >4 cm, the ERR increases to 8%–10%, but the tumour is nevertheless classified as low-risk.
<sup>e</sup>Formerly considered a type of FTC, Hurthle cell carcinoma has distinct clinical, biological and genetic features [24] that justify its recognition as a distinct type of DTC by the WHO [16]. Some authors consider it a more aggressive form of DTC. When associated with extensive vascular and/or capsular invasion, the recurrence risk should be classified as high. For minimally invasive Hurthle cell carcinoma, robust data are lacking on the true risk of recurrence.
<sup>f</sup>The BRAF V600E mutation is associated with aggressive histologic features, lymph node metastases and ETE, but its relative contribution to the risk of recurrence is not well-defined. Co-existing BRAF V600E and TERT mutations act synergically to increase the risk of recurrence [25, 26].

<sup>131</sup>I, iodine-131; ATA, American Thyroid Association; DTC, differentiated thyroid cancer; ERR, estimated risk of recurrence; ETE, extrathyroidal extension; FTC, follicular thyroid cancer; NIFTP, non-invasive follicular thyroid neoplasm with papillary-like nuclear features; PTC, papillary thyroid cancer; RAI, radioactive iodine; Tg, thyroglobulin; WHO, World Health Organization.
to treat persistent or recurrent disease (treatment of known disease) [8].

In all three cases, RAI administration must be followed by an iodine-131 ($^{131}$I) whole-body scan (WBS) to stage the disease and document the $^{131}$I avidity of any structural lesion. The estimated level of risk for persistent/recurrent disease will determine whether and how much RAI is given. Low activities are usually given for remnant ablation (30 mCi, 1.1 GBq); high activities ($\geq$100 mCi, 3.7 GBq) are used for treatment purposes. To optimise isotope uptake, RAI should be given after thyroid-stimulating hormone (TSH) stimulation, which can be achieved by withdrawing levothyroxine for 4–5 weeks, ideally until serum TSH levels reach $\geq$30 mIU/ml. Alternatively, recombinant human TSH (rhTSH) can be given (two daily injections of 0.9 mg of rhTSH followed by RAI on day 3). The resulting TSH level is not usually measured (unless doubts arise as to whether the injections have been properly administered). Levothyroxine withdrawal is preferred if distant metastases are present. The use of rhTSH is associated with superior short-term QoL [41].

As shown in Figure 2, practice guidelines unanimously recommend treatment with high RAI activities ($\geq$100 mCi, 3.7 GBq) for patients with high risk of recurrence [IV, A] [7–10, 42]; RAI administration is not recommended for certain low-risk patients [i.e. those with a small ($\leq$1 cm) intrathyroidal DTC and no evidence of locoregional metastases] [II, E] [43]. The term ‘very low-risk’ is often applied to these patients in the literature [7, 44]. There is less consensus regarding other low-risk DTC patients [IV, C] (see Table 3). In 2015, the ATA guidelines advised against the systematic use of RAI in the latter group [8]. However, the European Association of Nuclear Medicine (EANM) has not endorsed this recommendation [45], mainly because prospective RCT data showing that surveillance is non-inferior to RAI administration are lacking. The ATA, the EANM, the Society of Nuclear Medicine and Molecular Imaging (SNMMI) and the European Thyroid Association (ETA) have recently published a joint statement acknowledging the absence of high-quality evidence either for or against the postoperative use of $^{131}$I in low-risk patients [46]. They conclude that decisions should be taken on an individual basis, depending on tumour features (e.g. risk of recurrence) (see Table 3), patient-related factors (e.g. comorbidities, motivation, emotional concerns), health-care setting (e.g. availability and quality of thyroid surgeons, US, RAI imaging, Tg assays) and the local management team’s preferences. Lastly, the expected benefits of a given RAI dose should outweigh the risks associated with its administration, which include adverse events (AEs) and diminished QoL [43]. The usefulness of $^{131}$I therapy in low-risk TC patients is now being assessed in two large RCTs (NCT01837745—ESTIMABL2, NCT01398085—IoN). Two other RCTs (ESTIMABL1 and HiLo) conducted in low-risk DTC populations showed that, if RAI is given in these cases, low activities (30 mCi, 1.1 GBq) following rhTSH and high activities (100 mCi, 3.7 GBq) following levothyroxine withdrawal are equally likely to produce successful ablation [I, A] [47, 48]. This equivalence is also evident at the level of recurrence-free survival.

*aModified from the 2015 ATA ongoing risk stratification (response to therapy) system [8].

ATA, American Thyroid Association; DTC, differentiated thyroid cancer; RAI, radioactive iodine; RRA, radioactive iodine remnant ablation; stimTg, TSH-stimulated serum thyroglobulin; Tg, thyroglobulin; TgAb, anti-serum thyroglobulin antibody; TSH, thyroid-stimulating hormone; TT, total thyroidectomy.
Figure 1. Recommendations for surgical management of DTC patients.

*a Active surveillance may be the preferred option in older patients, at high surgical risk. Informed consent must be obtained for all subjects opting for an active surveillance programme.

*b Patients requiring neck dissection should be referred to high-volume specialised surgeons.

*c As determined by preoperative contrast-enhanced CT or MRI and/or endoscopy, R0/R1 resection is preferable with preservation of function.

CND, central neck dissection; CT, computed tomography; DTC, differentiated thyroid cancer; EBRT, external beam radiotherapy; ETE, extrathyroidal extension; LND, lateral neck dissection; MRI, magnetic resonance imaging; N0, no evidence of locoregional lymph node metastasis; N1, regional lymph node metastasis; R0, no residual tumour; R1, microscopic residual tumour; TT, total thyroidectomy; US, ultrasound.
as demonstrated by long-term follow-up data from the ESTIMABL1 and HiLo trials [49, 50]. RAI adjuvant therapy can be considered for intermediate-risk patients. Decisions on RAI dosage and TSH stimulation modalities are based on case features—surgical, clinical and pathological (particularly the extent of lymph node involvement and the aggressiveness of the pathological subtype) [IV, B] [43]. If given, low to high activities (30 mCi, 1.1 GBq to 100 mCi, 3.7 GBq) are recommended. In these patients, the ATA recommends individualised decision making [8].

Follow-up, long-term implications and survivorship

Follow-up tools and schedules (Figure 3) vary according to the tumour histotype, initial treatment, initial risk of persistent/recurrent disease (Table 3) and responses to treatment (Table 4). Serum Tg assays and neck US are the mainstays of DTC follow-up [51]. Patient management can be improved when health professionals collaborate as members of a multidisciplinary team.

Serum Tg. Serum Tg is a sensitive marker for the presence of thyrocytes, but it cannot discriminate between normal and malignant cells. Undetectable levels thus have high negative predictive values, but detectable values can be false-positives. To minimise variability, Tg levels should ideally be measured with the same assay [52]. Concomitant assessment of serum TgAb is mandatory, as these antibodies can interfere with Tg assays, causing false-negative or, less commonly, false-positive results [53]. Serum Tg can be assayed under basal conditions (i.e. during levothyroxine treatment) or after endogenous (levothyroxine withdrawal) or exogenous (rhTSH injection) TSH stimulation. In patients treated with total thyroidectomy plus RAI remnant ablation, stimulated serum Tg levels < 1 ng/ml are highly predictive of an excellent response to therapy, and subsequent stimulated Tg assays are unnecessary [54]. High-sensitivity (<0.2 ng/ml) assays of basal Tg levels can also be used to verify the absence of disease (excellent response) [II, B] [55]. If negative imaging findings are accompanied by detectable Tg levels, the treatment response is classified as indeterminate or biochemical incomplete (Table 4). In this case, the positive predictive value increases with the serum Tg level or, if serial measurements are available, with levels that increase over time. Almost 60% of patients who have total thyroidectomy without postoperative RAI administration will have basal serum Tg levels > 0.2 ng/ml [56, 57], which indicates an
absence of disease (i.e. an excellent response to therapy). When serum Tg levels are detectable, serial measurements of Tg should be obtained on levothyroxine treatment [IV, B] [56, 57]. A similar approach might be used following lobectomy [IV, C] [28]. Increasing Tg levels are highly suspicious for persistent/recurrent DTC, and the same may be true for rising TgAb levels.

Neck US. Neck US is the most effective tool for detecting structural disease in the neck, particularly when remnants of normal thyroid tissue are present. Combined with the results of FNA cytology [58] and serum Tg assays, neck US findings can achieve an accuracy of nearly 100% [59]. The shortcomings of US include substantial operator dependency [60], a high frequency of non-specific findings [61] and the possibility of unsatisfactory visualisation of deep structures and those acoustically shadowed by bone or air. The latter sites are better explored with cross-sectional imaging modalities (see below). Abnormal US findings can be classified as indeterminate or truly suspicious (Table 5) [62, 63]. Unlike PTC, FTC metastasis is typically haematogenous and rarely involves the locoregional lymph nodes, so neck US in these cases serves mainly to exclude residual/recurrent thyroidbed disease.

Other imaging studies. Other imaging studies should be ordered if locoregional and/or distant metastases are known to be present [IV, A] or suspected (based, for example, on rising serum Tg or
TgAb levels in the absence of sonographically identifiable neck disease or in patients with intermediate-to-high risks of persistent/recurrent disease, irrespective of the neck US findings) [IV, B] [8].

A WBS can be carried out after the administration of diagnostic or therapeutic doses of RAI. Because its sensitivity is low (27%–55%), diagnostic WBS is not indicated during follow-up [IV, A] [64]. Uptake is highly specific (91%–100%) for the presence of thyroid tissue, but false-positive results are possible. In these cases, single-photon emission computed tomography or computed tomography (CT) offers better anatomic resolution [64].

[18F]2-Fluoro-2-deoxy-D-glucose—positron emission tomography (FDG–PET) combined with CT is useful for assessing the extent of disease and defining the prognosis [65, 66]. Its sensitivity is around 94%, and specificity is between 80% and 84%. FDG–PET is more sensitive than therapeutic WBS for detecting persistent disease in patients with negative cross-sectional imaging studies, serum Tg levels >10 ng/dl, and/or aggressive histotypes (e.g. aggressive PTC, poorly differentiated TC, widely invasive follicular carcinoma) [67]. FDG uptake is associated with a worse prognosis and refractoriness to RAI treatment [68, 69], but it is not a reliable predictor of tumour growth [70]. FDG–PET is the first-line isotopic imaging technique for patients with RAI-refractory disease.

Cross-sectional imaging modalities should be chosen on the basis of the anatomic region to be explored. CT is best for neck and chest imaging. Contrast enhancement is used for studies of the neck and mediastinal lymph nodes but not for the lungs. All forms of RAI treatment should be deferred for at least 6 weeks after administration of any ioddinated contrast medium. Contrast-enhanced magnetic resonance imaging (MRI) is appropriate for exploring the neck, liver, bones and brain [64]. MRI of the neck is subject to substantial image degradation due to respiratory motion, and a CT scan is often a better alternative. Suspected aerodigestive-tract involvement should always be assessed endoscopically.

Follow-up strategies. All patients with DTC should have neck US and serum Tg and TgAb assays 6–18 months after primary treatment (surgery ± RAI therapy). The subsequent follow-up schedule will depend on the initially estimated risk of persistent/recurrent disease and responses to therapy (Figure 3).

PTC patients at low risk for recurrence who have no evidence of structural disease at the first follow-up visit can be monitored with periodic (12–24 months) Tg and TgAb assessments. Repeat neck US scans can be carried out as needed, depending on serum Tg and TgAb levels [71]. The same schedule can be adopted for intermediate-risk PTC patients with excellent responses to treatment [IV, A] [27, 30, 44]. TSH levels should be maintained in the low-normal range (0.5–2 μIU/ml) [IV, B] [8]. The follow-up protocol for minimally invasive FTCs is often the same used for low-risk FTCs, although the evidence supporting such an approach is insufficient [V, C] [24].

Low- or intermediate-risk PTC patients with a biochemical incomplete or indeterminate response to treatment should have serum Tg and TgAb assays and a neck US every 6–12 months. Rising Tg or TgAb levels warrant further imaging studies [72]. Mild TSH suppression should be considered (0.1–0.5 μIU/ml) in patients at intermediate risk of recurrence [IV, B] [8]. In patients with high-risk PTCs, poorly differentiated TCs or widely invasive FTCs, serum Tg and TgAb levels should be assessed every 6–12 months if the response to therapy is excellent or biochemical indeterminate/incomplete. Cross-sectional or functional imaging studies should be repeated if detectable Tg levels persist [IV, B] [27, 30]. For patients whose recurrence risk is initially classified as high, a more in-depth imaging work-up may be advisable even if serum Tg levels remain or become undetectable, as the absence of the circulating Tg may simply reflect the dedifferentiation of any residual tumour tissue that might be present [8]. Serum TSH levels should be suppressed in all patients with biochemical incomplete or indeterminate responses to treatment (0.1–0.5 μIU/ml) [IV, B] [8]. Patients with structural incomplete responses can be placed on active surveillance or referred for local or systemic treatments.

Management of advanced/metastatic disease

Distant metastases occur in fewer than 10% of patients with DTC. Half are present when the tumour is first discovered; the others are found later, sometimes decades after initial treatment. Metastases are observed most frequently in patients with aggressive histological subtypes (e.g. tall-cell, hobnail, solid, diffuse sclerosing and columnar-cell variants); vascular invasion, large primary tumours, macroscopic extrathyroidal extension, bulky locoregional nodal disease [8]. The most common sites are lungs and bones (involved in 49% and 25% of all cases, respectively), and in 15% of cases, both are affected [73]. Bone metastases are more common in FTC than in PTC (55.5% versus 31.5%, respectively). Spinal (34.6%) and pelvic (25.5%) bones are the most frequently involved, followed by those of the chest (18.3%), extremities (10.2%), shoulder girdle (5.4%) and the
RAI therapy. Patients with distant metastases should receive 100–200 mCi (3.7–7.4 GBq) of 131I after TSH stimulation [IV, A] [73]. The latter can be achieved with levothyroxine withdrawal or, if withdrawal is clinically contraindicated or the patients has hypopituitarism, with injections of rhTSH (Figure 2). One-third of patients have lesions that are not RAI-avid and are considered RAI-refractory [IV, A] (Figure 2) [73, 76]. If the distant metastases are RAI-avid, 131I is administered every 6 months for 2 years and less frequently thereafter. Between treatments, suppressive doses of levothyroxine are given to maintain serum TSH levels below 0.1 µIU/ml (unless there are specific contraindications) [III, B] [77–79]. Data from some prospective cohort studies suggest that disease progression, recurrence and death rates are reduced in patients undergoing TSH suppression for structurally identifiable disease [77, 79], but it is still unclear how much suppression is appropriate [78]. Between treatments, efficacy should be verified with periodic cross-sectional imaging studies. Compared with repeated administrations of standard doses of RAI (100 mCi or 3.7 GBq), use of higher, dosimetrically determined activities appears to offer no benefits in terms of OS [80]. When distant metastases lose their ability to concentrate RAI or structural progression occurs within 6–12 months after RAI administration, the disease is considered RAI-refractory [IV, A] (Figure 2) [73, 76]. A cure is unlikely if lesions persist after administration of a cumulative dose of 600 mCi 131I, and decisions on whether to continue RAI therapy will be based on tumour burden, RAI-uptake intensity and responses to previous RAI administrations [73].

Overall, one out of three patients with distant metastases will be cured with RAI and have a near-normal life expectancy [73]. These are usually young individuals with well-differentiated TC and small non-FDG-avid metastatic lesions. The other patients will at some point be classified as RAI-refractory; the prognosis in these cases will vary, depending mainly on the tumour burden and growth rate. Overall, their 5-year survival is <50%. RAI refractoriness, however, remains uncommon, with an estimated incidence of 4–5 cases per million population. Drugs for reinducing or increasing RAI uptake by the tumours are currently under investigation. The selective kinase inhibitors dabrafenib [81], vemurafenib [82] and selumetinib [83] can reportedly restore RAI uptake and tumour responses in selected patients, especially in those with small tumour burden and low progression rate. Several trials are underway to validate these preliminary data (NCT02344956, NCT02456701, NCT02145143, NCT02152995, NCT03363347), but thus far, none of the three drugs has been approved for this indication.

Locoregional therapy. Several locoregional approaches can be used to treat TC. The data and indications discussed below, however, are based mainly on studies of other solid tumours. Specific recommendations are lacking for DTC or MTC patients; therefore, the indications for locoregional treatments of these tumours will be discussed together. ATC patients will be discussed separately, as their poor prognosis is a major factor in all treatment decisions.

Bone metastases: The relatively long survival perspective places TC patients with bone metastases at high risk of skeletal-related events (SREs), i.e. pathological fractures, spinal cord compression, need for radiation (for pain or impending fracture) or surgery and hypercalcaemia. Up to 37% of TC patients experience SREs, and they are associated with poorer prognoses [84, 85].

There is a strong rationale and some clinical data supporting the roles for bone resorption inhibitors (bisphosphonates or denosumab) [V, B], external beam radiotherapy (EBRT) or other locoregional treatments in reducing SREs [86]. Bisphosphonates and denosumab have each been shown to decrease SRE rates and bone pain associated with breast, prostate and lung cancers. Inhibition of bone resorption should be considered in TC patients with multiple bone metastases. Treatment can be administered every 4 weeks (bisphosphonates and denosumab) or every 3 months (bisphosphonates). The optimal duration of treatment is unknown, but in other more thoroughly studied tumours (e.g. breast, prostate, lung), a minimum of 2 years is recommended. Adequate calcium and vitamin D levels should be maintained during treatment. The most significant AE of these drugs is jaw osteonecrosis, and the risk is increased in patients receiving antiangiogenic therapy [87]. A baseline dental evaluation is thus mandatory before starting treatment with bone resorption inhibitors, and regular checkups are recommended during treatment.

If the bone metastases are RAI-avid, RAI therapy may control the disease for some time and alleviate or delay symptoms, but it is unlikely to eliminate these lesions. Locoregional treatments may allow longer progression-free intervals and even cures in patients with targetable, oligometastatic bone disease. Surgery followed by EBRT is associated with the best outcomes, at least for limb lesions [88]. If surgery is not feasible, bone lesions associated with pain or a high fracture risk should be treated with fractionated (20 Gy in five fractions or 30 Gy in 10 fractions) or single-fraction (8 Gy) EBRT and/or with interventional radiology techniques, including cementoplasty and thermal ablation [89]. For spinal cord compression in a patient whose life expectancy exceeds 6 months, longer fractionation schedules (e.g. 30 Gy in 10 fractions over 2 weeks) are recommended. If the life expectancy is ≤6 months, a single fraction of 8 or 20 Gy in five fractions should be used to minimise hospitalisation [II, B] [90].

Percutaneous vertebroplasty can reduce the pain and deformity associated with vertebral body fractures. The efficacy of this innovative approach has not been directly compared with surgery and should only be done in high-volume centres to minimise the risk of complications (e.g. cement leakage outside the bone). There is limited evidence that other conservative techniques [radiofrequency ablation (RFA), cryotherapy] are effective for treating TC-related bone lesions [V, B] [91].

Palliative EBRT alleviates pain and neurological complications. Pain relief is often achieved 48–72 h after treatment, although it may take up to 1 month.
**Lung metastases:** The lung is a common site of TC metastasis. The lesions are usually multiple, bilateral, of varying size (from a few millimetres to 1 cm) and asymptomatic. Metastasectomy is not the standard approach for these lesions, but it may be considered for oligometastasis in patients with good performance status (PS) [V, C]. RFA is also a possibility for solitary lesions or those causing a specific symptom due to their volume and location [V, C]. RFA is considered for lesions <2–3 cm in patients not eligible for surgery or those requiring an extensive resection [92].

**Liver metastases:** Liver metastases are rare in DTC but more common in MTC. Liver involvement usually presents with multiple lesions, but if true solitary lesions are detected, they may be candidates for local ablation. In MTC patients with a dominant lesion that is growing more rapidly than the background disease, local ablation (e.g. RFA) may be useful for controlling symptoms, systemic ones in particular, such as diarrhoea. The outcome of RFA will depend on the size of the lesion (optimally <30 mm), its location (at least 3 mm from all vessels) and its visibility on US. Direct comparisons of surgery and RFA are lacking. In general, individuals who are ineligible for surgery are not the best candidates for percutaneous ablation. If both surgery and RFA are contraindicated, hepatic intra-arterial embolisation with drug-eluting beads might be an option: it has been used in other solid tumours [93] but its efficacy in TC has not been validated.

**Invasion of upper aerodigestive tract:** Invasion of the upper aerodigestive tract should always be excluded in TC patients with locoregional disease. Suspicious symptoms include haemoptysis and dysphagia. Contrast-enhanced CT and/or MRI are helpful for exploring suspicious cases, although endoscopy is more definitive. In selected cases (e.g. bleeding, exophytic lesions), local treatment (e.g. laser excision) is advisable before starting antian- giogenic multikinase inhibitor (MKI) therapy.

**Systemic therapy and personalised medicine.** TSH suppression (serum level <0.1 µIU/ml) is recommended for all TC patients with persistent structural disease in the absence of specific contraindications [III, B] [77]. Not all patients with RAI-refractory disease require systemic MKI therapy immediately. The treatment strategy should be based on multiple factors, including...
symptoms, tumour burden, the Eastern Cooperative Oncology Group (ECOG) PS, lesion characteristics (e.g. paratracheal location or other features likely to cause symptoms) and disease progression [defined using Response Evaluation Criteria in Solid Tumours (RECIST) v1.1 as a 20% increase in the sum of target lesions or the appearance of new lesion] [94] (Figure 4). Importantly, decisions on whether or not to use MKIs must always be based on patient preference after a careful discussion with the managing physician of the expected benefits and risks associated with specific drugs. Temporal trends in the levels of serum tumour markers (e.g. Tg doubling time) can be used to support and help decision making [95]. Importantly, however, an increase in serum Tg levels in the absence of radiologically evident disease progression should not be used to select patients requiring systemic therapy. A complete cross-sectional imaging assessment of the extent of the disease is mandatory for any treatment decisions. RECIST v1.1 are used to define target lesions and measure responses to systemic treatment [94]. The imaging assessment should be repeated every 3–12 weeks during treatment. Reductions in serum Tg are expected in responders, but clinical decisions cannot be based on this parameter alone.

**First-line systemic therapy:** Lenvatinib and sorafenib should be considered the standard first-line systemic therapy for RAI-refractory DTC [1; A; ESMO-Magnitude of Clinical Benefit Scale (ESMO-MCBS) v1.1 scores: 3 for lenvatinib, 2 for sorafenib]. Lenvatinib and sorafenib have been approved by the European Medicines Agency (EMA) and the United States Food and Drug Administration (FDA) for progressive, metastatic, RAI-refractory DTC. Both drugs have been investigated in two large, randomised phase III trials (sorafenib in DECISION [96], lenvatinib in SELECT [97]). Head-to-head comparisons of the two agents have not been undertaken. They cannot be compared based on their performances in the RCTs cited above, which differed substantially in terms of enrolment criteria. Unlike the DECISION population, participants in SELECT underwent mandatory assessment of radiological disease progression at entry by an independent committee, and pre-treated patients were not excluded. In addition, progression-free survival (PFS) in the placebo arm of SELECT was shorter than that of DECISION, which also suggests that the SELECT trial population may have had more advanced or more active disease than that of the DECISION study.

In the DECISION trial, 417 patients were randomised (1 : 1) to treatment with sorafenib (400 mg twice daily) or placebo, with crossover permitted at disease progression [96]. The study demonstrated that sorafenib significantly prolongs PFS [median PFS (mPFS) 10.8 versus 5.8 months with placebo, hazard ratio (HR) 0.59, 95% confidence interval (CI) 0.45–0.76, P = 0.001]. Objective responses (all partial) occurred in 12% of the sorafenib group and 0.5% of placebo-treated patients (P < 0.0001). The median response duration was 10.2 months (95% CI 7.4–16.6). Stable disease lasting ≥6 months (post hoc analysis) was observed more frequently with sorafenib (82/196 patients, 41.8% versus 67/202 patients, 33.2% in the placebo group). Disease control (partial response or disease stability lasting ≥6 months; post hoc analysis) was achieved in 106/196 patients (54.1%) treated with sorafenib and 33.8% (68/201 patients) of those receiving placebo (P < 0.0001). Most patients (71.4%) receiving placebo crossed over to sorafenib, and 20.3% of patients in sorafenib arm and 8.6% of patients in placebo arm received additional therapies. OS was similar in the two arms (HR 0.80, 95% CI 0.54–1.19, P = 0.14), and the median OS (mOS) had not been reached at the data cut-off (31 August 2012). The median durations of treatment were 10.6 months (interquartile range 5.3–15.7) with sorafenib and 6.5 months (3.3–12.9) with placebo.

In the SELECT trial, 392 patients were randomised 2 : 1 to receive lenvatinib or placebo [97]. The study met the primary aim, demonstrating that lenvatinib significantly prolonged PFS compared with placebo, as first-line therapy (mPFS 18.3 versus 3.6 months in the placebo arm, HR 0.21, 99% CI 0.14–0.31, P < 0.001) and in pre-treated patients (mPFS 15.1 months). The 6-month PFS rates were 77.5% (lenvatinib group) and 25.4% (placebo group). Responses to lenvatinib (complete in four cases) were observed in 64.8% patients (compared with 1.5% in the placebo group) (OR 28.87, 95% CI 12.46–66.86, P < 0.001). Responses occurred rapidly (median time to objective response: 2 months, 95% CI 1.9–3.5). The drug’s activity varied with the site of disease, with lung and lymph node lesions responding very

*Second-line therapy.

DTC, differentiated thyroid cancer; PFS, progression-free survival; RAI, radioactive iodine.
well, and liver and bone metastases less so [98]. mOS rates in the two arms were not significantly different (HR 0.73, 95% CI 0.50–1.07, P = 0.10), but subgroup analysis revealed significantly improved OS in patients >65 years treated with lenvatinib (HR 0.53, 95% CI 0.31–0.91, P = 0.020). In this trial, TC appeared to be more aggressive in older people, as reflected by the mOS of 18.4 months (95% CI 13.3–20.3) reached in placebo-treated patients >65 years compared with that in younger subjects, which had not been reached when the results were published [99].

The optimal sequence of MKIs in RAI-refractory DTC cannot be determined based on currently available evidence. Previous MKI therapy is not a contraindication for subsequent use of these drugs, but data on second-line efficacy are scarce [II, C]. MKIs should be continued until the disease progresses, unacceptable toxicities occur or the patient asks to stop treatment. In the presence of single-site progression, locoregional treatment (e.g. EBRT, embolisation, percutaneous treatment modalities) can be done for local control, without discontinuing MKIs [V, C]. Data on real life experiences with lenvatinib in DTC patients are now available and as expected, the drug’s efficacy was not as good as that observed in highly selected RCT populations [100, 101]. Other antiangiogenic agents have been tested as first-line therapy in phase II trials, with widely varying response rates (Table 6) [102–110]. None of these agents has been approved yet for RAI-resistant DTC. MKIs with specific targets (e.g. BRAF, tropomyosin receptor kinase (TRK)) have also been used. Vemurafenib has reportedly displayed activity against BRAF V600E TCs in both MKI-naive [overall response rate (ORR) 38.5%, 95% CI 20.2–59.4] and pre-treated patients (ORR 27.3%, 95% CI 10.7–50.2) [81, 111]. Larotrectinib has been recently approved by the FDA and the EMA for all paediatric and adult cancers expressing the TRK gene fusion protein. Partial responses were observed in all five TC patients treated with this drug in a recently reported phase I/II trial [112]. There is a biological rationale for treating advanced TCs with antiangiogenic agents plus immune checkpoint inhibitors [113], and an RCT is currently underway to assess the activity of lenvatinib plus pembrolizumab in this setting (NCT02973997).

**AEs of MKIs:** AEs occurred in 98.6% of patients receiving sorafenib during the DECISION trial [96]: hand–foot syndrome, diarrhoea, alopecia, rash or desquamation, fatigue, weight loss and hypertension were the most common. Serum TSH levels exceeding 0.5 µIU/ml were observed in 33.3% patients (69/207) in the sorafenib arm. TSH increases are a recognised AE of sorafenib and other MKIs, and levels should be checked monthly to ensure that suppression is maintained.

Serious AEs were documented in 37.2% (77/207) of the sorafenib-treated participants. Nine developed a second malignancy: squamous-cell skin cancer in seven cases (one patient also had melanoma), acute myeloid leukaemia and bladder cancer in the remaining two cases. Skin cancer is a consequence of sorafenib’s paradoxical activation of mitogen-activated protein kinase signalling in keratinocytes harbouring mutated or activated RAS. In clinical practice, skin cancer can be resected surgically with curative intent and sorafenib continued, but monitoring and early intervention for skin lesions is essential. The high rate of AEs inevitably diminishes treatment compliance. In DECISION, where the mean daily dose was 651 mg, AEs frequently led to treatment interruptions (137/207 patients, 66.2%), dose reductions (133 patients, 64.3%) or drug withdrawals (39 patients, 18.8%).

In SELECT, at least one side-effect also occurred in all lenvatinib-treated patients [114], the most common being hypertension, diarrhoea, fatigue, proteinuria, rash and hand–foot syndrome. Treatment interruptions (82.4% of patients) and dose reductions (67.8%) led to a mean daily lenvatinib dose of 17.2 mg [97]. AEs generally occurred during the first few weeks of treatment and decreased rapidly after treatment is interrupted. A trial comparing lenvatinib starting doses of 24 versus 18 mg is currently recruiting (NCT02657369). More selective agents such as larotrectinib for TRK fusion-positive cancers and highly selective RET inhibitors (e.g. LOXO 292, BLU 667) have better toxicity profiles. Off-target side-effects are uncommon with these drugs, and toxicities are mild and manageable, mostly of grades 1 and 2 [112, 115].

Physicians, patients and caregivers should be aware of these AEs. Caught early, they can be effectively managed, but prevention, when feasible, is always advisable [116]. The aim should be to manage the side-effects successfully without resorting to dose or treatment schedule adjustments, which can have detrimental effects on treatment efficacy. A *post hoc* analysis of the impact of dose interruption on lenvatinib efficacy in SELECT trial participants revealed that longer interruptions and lower mean dose intensities may diminish the potential benefit conferred by the drug [117]. As MKIs may cause fatal harm when administered to a pregnant woman and may result in reduced fertility in both sexes, fertility preservation approaches should be discussed before treatment starts [118].

**Conventional cytotoxic therapy:** The results of chemotherapy (CTh) administration (e.g. doxorubicin) in RAI-refractory DTC are disappointing; therefore, it is not recommended unless MKI therapy is contraindicated.

### ATC

#### Diagnosis and pathology/molecular biology

ATCs are very rare tumours that usually present at an advanced stage, display extremely aggressive behaviour, and are associated with a very poor prognosis. They are morphologically heterogeneous and must be distinguished from other neck tumours, including squamous carcinoma of the larynx, sarcomas and lymphomas. Preoperative biopsy assessment includes diagnostic immunomarkers that can differentiate ATC from large cell lymphoma or pleomorphic sarcoma. The molecular profile of ATC includes mutations of the TERT promoter (associated with *BRAF* or *RAS* mutations) and *TP53* [21, 22], as well as targetable abnormalities (e.g. *NTRK* and *ALK* rearrangements).

#### Staging and risk assessment

In the eighth edition of the UICC TNM staging system [23], diagnosis of ATC is no longer associated with pT4 stage by default. Cases treated with resection are staged like other TC histotypes, based on tumour size and extension (Table 2).
ATCs are considered one of the most aggressive solid tumours in humans. The median survival after the initial diagnosis is ~4 months and only one out of five patients survives more than 12 months (1-year survival rates: 10%–20%). Long-term survival has been reported, but the estimated rate at 10 years is <5%. The dismal prognosis stems from the fact that over 40% of the patients present at diagnosis with large primary tumours (mean size: 6 cm), gross extrathyroidal extension and locoregional and distant metastases, which make complete resection unlikely [119]. A thorough imaging work-up should be carried out soon after the diagnosis. The FDG–PET-CT scan is the most sensitive tool for documenting the extent of disease. Scans should be repeated at all stages of treatment [120].
Management of local/locoregional disease

Surgery. ATC is rarely amenable to complete resection (Figure 5). Total thyroidectomy with bilateral central neck dissection may be carried out in those very rare cases of localised ATC in M0 patients. Extensive resection with total laryngectomy, oesophagegectomy and/or resection of the great vessels has been reported in highly selected cases in specialised centres, but postoperative mortality and morbidity are high and there is no high-level evidence to indicate that this approach improves survival. The prognosis is also unaffected by incomplete palliative resection (R2) or ‘debulking’, which is not generally recommended [IV, E] [121]. Tracheostomy may be needed to alleviate symptoms in patients with moderately progressive disease, but the impact of tracheostomy on QoL must be considered. Given the technical complexity, the procedure is generally done under general anaesthesia. An experienced team of surgeons and anaesthesiologists is essential, as is a complete preoperative cross-sectional imaging assessment of the trachea and tumour.

Radiotherapy. Optimal outcomes in terms of survival and local disease control in ATC require complete or near-complete [no residual tumour (R0) or microscopic residual tumour (R1)] resection followed by high-dose EBRT, with or without concomitant ChT [V, A] [122, 123]. However, this multimodal approach can strongly impact QoL and should be reserved for carefully selected patients to ensure clinical benefit. Timely discussion within a multidisciplinary team setting is strongly recommended [V, A] (Figure 5).

Analysis of 1200 ATC cases in a large national database [121] revealed significantly better outcomes when multimodality therapy included radical surgery (HR 0.35, 95% CI 0.28–0.43, P < 0.0001 versus no surgery or palliative surgery), 40 Gy of EBRT (HR 0.46, 95% CI 0.38–0.56, P < 0.0001 versus no EBRT or <40 Gy EBRT) and ChT of any type (HR 0.63, 95% CI 0.52–0.76, P < 0.0001 versus no ChT). Outcomes also varied with UICC stage. For stage IVA disease, the benefit from additional therapies was nonsignificant. For stage IVB disease, however, radical surgery followed by both EBRT and ChT significantly improved cause-specific survival compared with radical surgery alone or with EBRT (HR 0.45, 95% CI 0.25–0.81, P = 0.0083).

A meta-analysis of 17 retrospective studies including 1147 patients looked at the impact of postoperative radiotherapy (PORT) after radical ATC resection and found that it significantly reduced the risk of death as compared with radical resection alone (HR 0.556, 95% CI 0.419–0.737, P < 0.001) [124]. Exploratory analyses demonstrated that PORT might also confer a survival benefit in patients with stage IVA (HR 0.364, P = 0.012) or IVB (HR 0.460, P = 0.059) disease but not for stage IVC. For best outcomes, PORT must be delivered as soon as possible after surgery [IV, A], but the patient must have recovered from surgery sufficiently to be able to lie flat and tolerate immobilisation.

Because of the improved dose distribution and the ability to reduce toxicity, intensity-modulated radiotherapy (RT) is the recommended approach [IV, C] [125]. There is some evidence of a dose–response relation. Outcomes in ATC are improved with doses exceeding 45–50 Gy [126, 127]. An analysis of the United States National Cancer Database showed maximal benefits with doses >60 Gy [128]. Evidence that hyperfractionated accelerated RT (i.e. delivery of two or more fractions per day over a shorter treatment time) improved survival over that obtained with conventional fractionation is insufficient, whereas it was clearly associated with increased toxicity [129–131].

For stage IVA or IVB disease, concomitant ChT (usually with doxorubicin or a platinum agent) has been used. Most of the data reported on this approach came from single-institution series and the clinical benefits reported have been variable. It has been shown that concomitant taxane therapy has radio-sensitising effects [132].

Palliative EBRT: In patients with unresectable disease, EBRT has a role in symptom control [V, C] [133]. The aim is usually to reduce the rate of growth of the neck mass and thereby the pressure symptoms. Fractionation schedules vary according to the individual patient (most commonly from 20 Gy in five fractions to 30 Gy in 10 fractions). These fractionation regimens allow simple beam arrangements such as parallel opposed or simple three-dimensional conformal techniques, so that RT can be started as soon as possible.

Management of advanced/metastatic disease

Systemic therapy and personalised medicine. Novel systemic therapies are urgently needed to improve the generally poor outcomes associated with ATC. Clinical trial enrolment should therefore be encouraged for patients with good clinical PS [V, B]. For patients ineligible for systemic treatments or clinical trials, best supportive care should be discussed (Figure 5) [133].

To date, cytotoxic ChT has been the primary treatment for metastatic disease, but it is associated with very low response rates and significant toxicities [133]. Recommended regimens consist of single-agent therapy with paclitaxel or doxorubicin or combined treatments (e.g. carboplatin/paclitaxel, docetaxel/doxorubicin) administered weekly or every 3–4 weeks [134–136]. No data are available to guide decisions on second-line therapy [133]. Chemoradiotherapy can be considered for local control of unresectable stage IVB disease, ideally with weekly administration of radio-sensitising ChT (see above).

Several novel approaches (targeted therapy, immunotherapy) are being studied, alone or in combination, to improve the poor response rates achieved with current strategies. The efficacy of lenvatinib in ATC is controversial. In 2015, the drug was approved by the Japanese regulatory agency for treatment of TCs, including ATC, based on data from a single-arm, open-label, phase II study conducted on a population of 51 patients [137], 17 of whom had ATC. The primary aim was to establish the drug’s safety in this setting. The ATC patients had an mPFS of 7.4 months (95% CI 1.7–12.9), an mOS of 10.6 months (95% CI 3.8–19.8) and an objective response rate of 24%. These findings prompted an international, multicentre, phase II trial, but the trial was stopped early due to futility (NCT02657369).

Molecular profiling studies have begun to elucidate the molecular drivers and the multistep dedifferentiation associated with ATC tumourigenesis [21, 22]. Early mutation of BRAF and RAS has been reported in 25% and 28% of the cases, respectively [138]. In a phase II, open-label basket trial, patients with BRAF
V600E-positive malignancies (including 16 with ATC) were treated with the BRAF inhibitor dabrafenib (150 mg twice daily) plus the MEK inhibitor trametinib (2 mg once daily). The ORR was 69% (11/16; 95% CI 41%–89%), and the treatment was well tolerated [139]. In May 2018, this combination received FDA approval for the treatment of locally advanced or metastatic ATC with the BRAF V600E mutation. If available, this should be the first-line therapy for advanced BRAF V600E ATC patients [V, B]. Other rare mutations and genetic aberrations may also prove to be druggable, such as ALK translocations [21, 22]. Extended molecular profiling of ATCs should be strongly encouraged as it may reveal promising possibilities for targeted therapies.

In the presence of non-druggable mutations, targeting the tumour microenvironment or common cancer signalling pathways is an alternative approach. ATC immunoprofiling has revealed high numbers of tumour-infiltrating lymphocytes in the tumour and tumour cell expression of programmed death ligand 1 (PD-L1) [138]. Immunotherapy with antibodies targeting programmed cell death 1 (PD-1) receptor or PD-L1 has produced impressive results in many malignancies, but few data are available on their use in ATC. The anti-PD-1 monoclonal antibody spartalizumab was tested in 41 heavily pre-treated patients with advanced ATC, and responses were observed in 19.5%, opening the road to the use of immunotherapy in ATC [140].

Inclusion of targeted therapy, immunotherapy, ChT and/or RT, administered in combination or sequentially, in multidisciplinary ATC management regimens may improve patient outcomes (NCT03181100).

**MTC**

**Diagnosis and pathology/molecular biology**

MTC is morphologically heterogeneous and can mimic virtually all other primary thyroid tumours. Demonstration of calcitonin (Ctn) expression is mandatory for the diagnosis. Rare primary Ctn-negative neuroendocrine carcinomas of the thyroid exist and must be distinguished from metastases from neuroendocrine neoplasms of the lung. In these cases, carcinoembryonic antigen (CEA) determination can be useful, being the only neck tumour expressing this marker. The preoperative diagnosis can also be challenging in the absence of a consistent immunophenotype.

RET and RAS proto-oncogene mutations are detected in ~90% of MTCs and are considered the predominant drivers of these tumours [141]. RET mutations occur sporadically, as somatic events, or can be inherited as germline events associated with familial MTC or the multiple endocrine neoplasia syndromes type 2A and 2B (MEN2A and MEN2B). A quarter of MTCs occur as part of an inherited syndrome, and germline RET mutations are present in up to 10% of the patients presenting with apparent-ly sporadic MTCs. All patients with MTC should thus be offered
genetic counselling and be screened for germline RET mutations [IV, A] [142, 143]. Strong genotype–phenotype associations affecting age at onset (most MTCs occur either in childhood or early adulthood) and tumour aggressiveness have been reported for specific germline RET mutations. MTCs harbouring somatic RET mutations are also commonly associated with more aggressive behaviour than that of their wild-type RET counterparts. The vast majority (91.4%) of sporadic MTCs with distant metastases harbour such mutations, in most cases RET M918T (93.8%) [144]. There is currently no evidence supporting the value of routine screening of MTC patients for somatic mutations. However, if treatment of advanced MTCs with selective RET inhibitors is planned, RET testing for somatic mutations is needed to individualise therapy [III, C].

Staging and risk assessment

The UICC system is recommended for staging all MTC patients, based on its utility in predicting disease-specific mortality [IV, A] [23]. The eighth edition of this system has introduced some important changes in the criteria used for staging thyroid tumours, including MTCs. Extrathyroidal extension, for example, is now important only when it is macroscopically evident (pT3b) [23]. In the absence of gross extracapsular extension, the primary will be staged solely on the basis of its size (pT1, pT2 or pT3a) (Table 2).

Ctn and CEA are valuable diagnostic, prognostic and predictive markers for use with MTC. Their serum concentrations are directly related to the C-cell mass [145, 146]. Preoperative Ctn levels correlate strongly with tumour diameter and postoperative Ctn levels. They can also provide useful preoperative information on the extent of the disease. An analysis of 300 consecutive cases of MTC treated with total thyroidectomy and compartment-oriented lymph node dissections found that preoperative serum Ctn levels <20 pg/ml (normal reference range: <10 pg/ml) were associated with almost no risk of nodal metastases [147]. Basal serum Ctn levels exceeding 20 pg/ml were associated with nodal
metastases to the ipsilateral compartments of the neck (central and lateral); higher levels were associated with increasingly extensive locoregional spread (levels >50 pg/ml: nodes of the contralateral central compartment of the neck; levels >200 pg/ml: nodes of the contralateral lateral compartment; levels >500 pg/ml: upper mediastinal nodes). Serum Ctn levels exceeding 500 pg/ml suggest distant metastatic disease and should be explored with additional whole-body imaging procedures. Serum Ctn should be measured 60–90 days after thyroidectomy. Patients whose postoperative basal serum Ctn level is normal (<10 pg/ml) are considered ‘biochemically cured’ and have a 10-year survival rate of 97.7%. However, 3% of patients with normal basal serum Ctn levels following thyroidec- tomy experience biochemical recurrence within 7.5 years [143]. CEA is not a specific biomarker for MTC, and serum assays are not informative for the early diagnosis of MTC. However, they are useful for monitoring the progression of clinically evident MTCs [IV, B] [148–150].

Doubling times for postoperative serum Ctn and CEA levels (defined as the interval of time in which the tumour markers levels have doubled) are established prognostic markers in MTC [IV, B] [148–150]. They are currently considered the best available predictors of tumour behaviour, recurrence and cancer-related death. A Ctn doubling time exceeding 6 months is associated with 5- and 10-year survival rates of 92% and 37%, respectively; shorter doubling times predict markedly worse survival (25% and 8% at 5 and 10 years, respectively) [148]. In patients with poorly differentiated and aggressive MTCs, Ctn values may actually decrease over time, whereas CEA levels increase [151]. Details on the use of Ctn and CEA doubling times are available below in the ‘Follow-up, long-term implications and survivorship’ section.

Management of local/locoregional disease

Surgery. Preoperative screening for pheochromocytoma and hyperparathyroidism is highly recommended for all patients with MTC (except in those already known to have MEN2B) [IV, A] [142, 143]. Neck US should be carried out to identify regional metastases; if sonographic (or clinical) findings are suspicious, contrast-enhanced CT of the neck and chest is indicated. Work-up for distant metastases, including chest CT, liver and axial bone MRI and 6-fluoro-(18F)-1-dihydroxyphenylalanine (FDOPA)-PET scan (if available), should be done if serum Ctn levels exceed 500 pg/ml or clinical findings are suspicious. Neck dissection, when needed, should be done by surgeons with substantial experience in TC surgery. The initial approach will depend on preoperative serum Ctn levels and neck imaging findings (Figure 6) [IV, B]. The guidelines in the algorithm are based on retrospective cohort studies [147, 152]. The grade B recommendation is based on the clinical benefits of elective neck dissection in patients with serum Ctn levels <500 pg/ml, for whom surgery may be curative.

For carriers of germline mutations, the recommended age for prophylactic total thyroidectomy depends on the type of mutation. Individuals with germline M918T mutations should undergo total thyroidectomy within the first year of life. For those with a C634F or A883F mutation (also considered high risk), surgery can be postponed until age 5 unless Ctn levels increase. Those with other mutations should be monitored from age 5 on with Ctn assays and neck US, and surgery should be done if Ctn levels increase or if the parents request it [143].

Follow-up, long-term implications and survivorship

Ctn and CEA monitoring should both be included in the early and long-term postoperative staging work-ups [IV, B] [150]. Serial measurements allow the calculation of doubling times, which provide useful information as described above. Currently available data indicate that Ctn doubling times should be based on at least four consecutive measurements, preferably obtained over a 2-year period [IV, C] [142, 143]. All measurements must be made by the same laboratory using the same assay. The ATA provides an online calculator for rapid determination of doubling times from user-supplied series of serum Ctn or serum CEA levels [153]. Figure 7 summarises MTC management strategies guided by Ctn and CEA levels and doubling times. Clinically relevant disease sites are rarely detected in patients with Ctn levels <150 pg/ml, but the likelihood of structural disease increases as Ctn and CEA levels rise.

Multiple imaging modalities should be used to identify locoregional and/or distant metastases [IV, B] [142, 143]. Contrast-enhanced whole-body (brain, neck, thorax, abdomen and pelvis) CT with ultra-thin reconstructions is sensitive and specific enough to allow one to estimate the burden of systemic disease and to assess and identify target lesions. Target and non-target lesions to assess are measured using RECIST v1.1 [94]. Contrast-enhanced MRI is more sensitive in identifying liver lesions, which can be misdiagnosed on CT or US as benign cystic lesions. US is useful for assessing neck lymph node involvement, although, as mentioned before, it sometimes provides inadequate visualisation of deep structures and those acoustically shadowed by bone or air. For these structures, CT and MRI are more sensitive, provide greater morphological detail, and are recommended when surgical interventions, EBRT or other locoregional ablative approaches are being planned. MRI is recommended for identifying or excluding brain metastases. Bone scans in MTC patients are high in sensitivity but low in specificity. Whole-body bone MRI without contrast medium offers higher specificity, particularly for osteoblastic lesions. Contrast enhancement is recommended when extrascapular extension or compression of the spinal cord or other neurological structures is suspected. Endoscopic exploration of the upper digestive tract and airways is mandatory whenever there is a high suspicion of infiltration.

As indolent tumours, MTCs generally display low avidity for FDG, so FDG–PET–CT is not recommended for their staging, but it can be useful for assessing advanced disease characterised by dedifferentiation and rapid progression [151]. FDOPA–PET has high sensitivity and specificity in MTC [154, 155] and it can reveal unidentified metastases or small lesions, but cost and availability issues make it unsuitable. Gallium-68 (68Ga) somatostatin analogue PET–CT is relatively insensitive and is not useful for staging, but it does reflect expression of somatostatin receptors, which is useful information when the feasibility of radionuclide therapy is being explored [156].
Table 7. Summary of recommendations

**Diagnosis and pathology/molecular biology**
- For all TCs, pathological diagnoses should be made according to the 2017 WHO classification [IV, A]
- All patients with MTC should be offered genetic counselling and screened for germline RET mutations [IV, A]

**Staging and risk assessment**
- The UICC TNM staging system (eighth edition) provides an estimated mortality risk. All prognostically relevant morphological parameters should be reviewed and described in the final pathology report [IV, A]
- The initial estimate of the risk of persistent/recurrent disease should be revised during follow-up to reflect the evolution of the disease and responses to treatments [IV, A]
- Doubling times for postoperative serum Ctn and CEA levels are established prognostic markers in MTC [IV, B]

**Primary tumour management**

**DTC**
- **Surgery**
  - Active US surveillance of the thyroid and neck lymph node (every 6–12 months) can be proposed for unifocal papillary microcarcinomas (<10 mm) with no evidence of extracapsular extension or lymph node metastases [III, B]
  - Lobectomy (instead of total thyroidectomy) may be proposed for selected low-risk (T1a–T1b–T2, N0) tumours [IV, B]
  - The use of prophylactic central neck dissection for low-risk tumours (T1b–T2, N0) varies from centre to centre [IV, C]. It may improve regional control for more invasive tumours (T3–T4) [IV, C]

- **RAI therapy**
  - RAI administration is not recommended for small (<1 cm) intrathyroidal DTC with no evidence of locoregional metastases (classified as low-risk cases) [II, E]. There is less consensus regarding other low-risk DTCs [IV, C]; if RAI is given, low activities (30 mCi, 1.1 GBq) following rhTSH administration are recommended [I, A]
  - RAI therapy may be considered in intermediate-risk patients (30mCi, 1.1GBq to 100 mCi, 3.7 GBq; rhTSH administration or levothyroxine withdrawal) [IV, B]; decisions on RAI dosage and TSH stimulation modalities are based on case features
  - Treatment with high RAI activities (≥100 mCi, 3.7 GBq; rhTSH administration or levothyroxine withdrawal) is recommended for patients at high risk of recurrence [IV, A]

**ATC**
- **Surgery**
  - ATC is rarely amenable to complete resection. Incomplete palliative resection (R2) or ‘debulking’ does not affect prognosis and is not recommended [IV, E]

- **Radiotherapy**
  - Optimal outcomes in terms of survival and local disease control in ATC require complete or near-complete (R0 or R1) resection followed by high-dose EBRT, with or without concomitant CHT [V, A]
  - For best outcomes, PORT must be delivered as soon as possible after surgery [IV, A]. IMRT is the recommended approach [IV, C]
  - Timely discussion by a multidisciplinary team is strongly recommended [V, A]

**MTC**
- **Surgery**
  - The initial surgical approach depends on preoperative serum Ctn levels and neck imaging findings [IV, B]

**Follow-up, long-term implications and survivorship**

**DTC**
- High-sensitivity (<0.2 ng/ml) assays of basal Tg can be used in lieu of TSH-stimulated Tg testing to verify the absence of disease (excellent response) [II, B]
- Serial measurements of basal Tg should be obtained in patients on levothyroxine treatment with residual thyroid tissue (i.e. those treated with total thyroidectomy and RAI remnant ablation that proved incomplete or with total thyroidectomy alone) [IV, B]. A similar approach might be used following lobectomy [IV, C]
- Neck US is the most effective tool for detecting structural disease in the neck, particularly when residual thyroid tissue is present
- Other imaging studies are indicated if locoregional and/or distant metastases are suspected [IV, B], or in patients with known metastases [IV, A]
- The follow-up protocol for minimally invasive FTCs is often the same one used for low-risk PTCs, although the evidence supporting such an approach is insufficient [V, C]
- TSH levels should be maintained in the low-normal range (0.5–2 μIU/ml) in all patients with excellent response to treatment and in low-risk patients with biochemical incomplete or indeterminate responses to treatment [IV, B]
- Mild TSH suppression should be considered (0.1–0.5 μIU/ml) in patients at intermediate to high risk of recurrence with biochemical incomplete or indeterminate responses to treatment [IV, B]

**MTC**
- Ctn and CEA monitoring should both be included in the early and long-term postoperative staging work-ups [IV, B]
- Multiple imaging modalities should be used to identify locoregional and/or distant metastases [IV, B]

Continued
Management of advanced/metastatic disease

Distant metastases are present at diagnosis in roughly 10% of all MTC patients, but higher rate (19%–38%) are encountered during follow-up [157]. Disease behaviour varies widely—indolent in some cases, rapidly progressive in others—and can be reliably predicted by Ctn and CEA doubling times. Advanced MTCs are invariably associated with the secretion of a variety of peptides (e.g. prostaglandins, kinins, vasoactive intestinal peptide, serotonin, histaminase), which can cause unpleasant symptoms such as flushing and diarrhoea. Management of these symptoms should be the first goal of treatment.

The systemic therapies currently approved for MTC have not been shown to improve OS, so evidence-based guidance is lacking on when to start these drugs and how patients with indolent disease should be followed. Decisions are based mainly on clinicians’ experience. Multidisciplinary input (e.g. from surgeons, endocrinologists, nuclear medicine physicians, medical and radiation oncologists, pain therapists and palliative care specialists) is strongly recommended to ensure optimal care for these patients. Active treatment (e.g. locoregional or systemic MKI administration) should be considered in the presence of symptoms, lesions close to vital structures, high-tumour burdens or disease progression (as defined by RECIST v1.1) [94].

Systemic therapy and personalised medicine.

First-line systemic therapy: Cabozantinib [1, A] and vandetanib [1, A; ESMO-MCBS v1.1 score: 2] are the first-line systemic treatments for progressive metastatic MTC. Their EMA and FDA

Table 7. Continued.

Management of advanced/metastatic disease

DTC

Radioactive iodine therapy

- Patients with distant metastases should receive 100–200 mCi (3.7–7.4 GBq) of 131I after TSH stimulation [IV, A]
- Non-RAI-avid lesions and those that lose their ability to concentrate RAI or progress despite RAI avidity should be considered RAI-refractory [IV, A]
- Between treatments, suppressive doses of levothyroxine are given to maintain serum TSH levels <0.1 µIU/ml (unless there are specific contraindications)

Locoregional therapy

- Single lesions that are symptomatic or progressive may be eligible for locoregional treatments (e.g. palliative surgery, EBRT, percutaneous therapies)
- Bone resorption inhibitors (bisphosphonates and denosumab) can be used alone or combined with locoregional treatments in the management of thyroid cancer-related bone metastases [V, B]
- There is limited evidence that conservative techniques (RFA, cryotherapy) are effective for treating TC-related bone lesions [V, B]
- Metastasectomy is not the standard approach for lung metastases but it may be considered for oligometastasis in patients with good PS [V, C]
- RFA is a possibility for solitary lung lesions or those causing a specific symptom due to their volume and location [V, C]
- Invasion of the upper aerodigestive tract should always be excluded in TC patients with locoregional disease

Systemic therapy and personalised medicine

- TSH suppression (serum level <0.1 µIU/mL) is recommended for all TC patients with persistent structural disease in the absence of specific contraindications [III, B]
- Decisions on whether or not to use MKIs must always be based on patient preference after a careful discussion with the managing physician of the expected benefits and risks associated with specific drugs
- Lenvatinib and sorafenib should be considered the standard first-line systemic therapy for RAI-refractory DTC [I, A; ESMO-MCBS v1.1 scores: 3 for lenvatinib, 2 for sorafenib]
- Cabozantinib [I, A] and vandetanib [I, A; ESMO-MCBS v1.1 score: 2] are the first-line systemic therapy for patients with progressive, metastatic MTC
- In patients with RETM918T or RAS-mutant MTCs, cabozantinib offers significant PFS and OS advantages over wild-type MTCs [II, C]
- There is little evidence to support the use of either CHT or radionuclide therapy in patients with MTC, although either might be considered when MKIs are contraindicated

<sup>a</sup>EMA approvals since January 2016.

<sup>b</sup>ESMO-MCBS version 1.1 [165]. The scores have been calculated by the ESMO-MCBS Working Group and validated by the ESMO Guidelines Committee.

<sup>c</sup>Substantial toxicity was reported but this was not captured by the current ESMO-MCBS toxicity penalty criteria and, consequently, toxicity adjustment could not be applied.

CI, confidence interval; EGFR, epidermal growth factor receptor; EMA, European Medicines Agency; ESMO-MCBS, ESMO-Magnitude of Clinical Benefit Scale; HR, hazard ratio; MKI, multikinase inhibitor; mPFS, median progression-free survival; OS, overall survival; PDGFR, platelet-derived growth factor receptor; PFS, progression-free survival; QoL, quality of life; VEGFR, vascular endothelial growth factor receptor.
 Both drugs inhibit RET kinase activity and are now under investigation. The RET-R918T-positive cases (HR 0.15, 95% CI 0.08–0.28, P < 0.0001) [161].

Although the ZETA and EXAM trials both focused on patients with advanced and/or metastatic disease, their designs and inclusion criteria were different. The markedly longer mPFS in the placebo arm of the ZETA trial—19.3 months [158] versus 4 months in EXAM [159]—suggests population differences. Indeed, unlike ZETA participants, those enrolled in EXAM had to meet RECIST criteria for disease progression and were thus likely to have more advanced disease. The results of the two trials are therefore not comparable, and there is no clear evidence supporting vandetanib over cabozantinib as first-line treatment. Both are active in first- and second-line regimens, both prolonged PFS compared with placebo and both displayed RET/RAS status-independent efficacy. The choice of which drug to use as first-line treatment may be based on potential toxicity in each patient (see below). However, cabozantinib, in a subgroup analysis, demonstrated a significant advantage in PFS and OS in patients with RETM918T or RAS-mutant MTCs [II, C] [161]. As noted for lenvatinib, recently released real world data on the efficacy of vandetanib in MTC patients are somewhat less encouraging than those generated in the highly selected population of RCTs [162].

Other anti-angiogenic MKIs (e.g. sorafenib, motesanib, pazopanib, sunitinib, lenvatinib) have already undergone phase II testing in advanced MTC patients. The most interesting results regarded sunitinib and lenvatinib, which were associated with response rates of 50% and 36%, respectively [157]. Thus far, however, no MKIs have been approved for second-line use. A randomised trial assessing the efficacy of nintedanib as second-line MKI therapy was prematurely closed due to flat enrolment (NCT01788982). The more selective RET inhibitors (e.g. LOXO-292-NCT03157128, BLU-667-NCT03037385) appear promising and are now under investigation. The RET-suppressing activity of these drugs is essential to their antitumour effects in MTC, whereas their anti-angiogenic activity is negligible.

Management of side-effects: AEs are very common during MKI therapy, and their management is critical for optimising these compounds’ therapeutic ratios. In the ZETA trial, 35% of the patients in the vandetanib arm required dose reductions and 12% discontinued treatment due to toxicity [158]. The most common

At high doses, vandetanib (150 mg) may result in much greater responses [157].

A combination with 5-fluorouracil and dacarbazine which did not result in much greater responses [157].

AEs associated with VEGF-pathway inhibition (e.g. hypertension, haemorrhage, fistula formation, gastrointestinal perforation) occurred more frequently among cabozantinib-treated patients than in those treated with placebo.

In the EXAM trial, 79% of patients in the cabozantinib arm had dose reductions, 65% interrupted treatment due to AEs, and 16% stopped treatment because of toxicities. Randomised trials are underway to assess the activities of lower, potentially less toxic doses of vandetanib (150 versus 300 mg, NCT01496313) and cabozantinib (140 mg capsules versus 60 mg pills, NCT01896479).

The preliminary results comparing the effects of the two doses of vandetanib in patients with advanced MTC have been posted on ClinicalTrials.gov and showed that the starting dose of 150 mg is equally effective as the high 300 mg dose in term of ORR.

Interruption of treatment and dose reductions are the most common means for managing AEs. Most decrease in intensity after a few days of withdrawal, but vandetanib AEs may be more persistent, given the drug’s 19-day half-life. However, frequent interruptions might reduce the efficacy of MKIs and/or trigger certain escape mechanisms. Most AEs (e.g. hypertension, diarrhoea) are well known and preventable. Useful guidelines for preventing and managing treatment-related AEs in these complex cases have been published by several societies. As for fertility preservation, the same measures taken for DTC patients are valid for those with MTC.

Conventional systemic ChT and radionuclide therapy: Systemically administered ChT has historically yielded poor results in MTC. The available data have been generated by retrospective analyses of small, single-institution cases series. The most active drugs have been doxorubicin alone or combined with cisplatin, which achieved a response in around 20% at best, or as a combination with 5-fluorouracil and dacarbazine which did not result in much greater responses [157].

Radionuclide therapy is an option in selected cases [III, C]. The activity of yttrium-90—DOTA-[D-Phe1-Tyr3]—octreotide (\(^{90}\)Y-DOTATOC) was tested in a phase II trial including 31 patients with metastatic MTC and increasing Ctn levels. Post-treatment decreases in Ctn levels (the primary endpoint) occurred in 29% of the patients treated, and survival benefits were also observed in the responders [164]. RCTs have not been carried out to compare the efficacies of radionuclide and MKI therapies. Ideally, this comparison should be done within a clinical trial setting. In short, there is little evidence to support the use of either ChT or radionuclide therapy in patients with MTC, although either might be considered when MKIs are contraindicated.

Methodology

These Clinical Practice Guidelines were developed in accordance with the ESMO standard operating procedures for Clinical Practice Guidelines development, http://www.esmo.org/Guidelines/ESMO-Guidelines-Methodology. The relevant literature has been selected by the expert authors. A summary of recommendations is provided in Table 7. An ESMO-MCBS table with MCBS scores is included in Table 8. ESMO-MCBS v1.1 was used to calculate scores for new therapies/indications approved by the EMA since 1 January 2016. [165]. Levels of evidence and grades of recommendation have been applied using the system shown in Table 9 [166]. Statements without grading were considered justified standard clinical practice by the experts and the ESMO faculty. This manuscript has been subjected to an anonymous peer-review process.

Acknowledgements

The ESMO Guidelines Committee would like to thank the ESMO Faculty and other experts who provided critical reviews of these ESMO Clinical Practice Guidelines.

Funding

No external funding has been received for the preparation of these guidelines. Production costs have been covered by ESMO from central funds.
